Abstract

The relationship between direct operating cost and departure noise annoyance was developed for commercial tilt rotor aircraft. This was accomplished by generating a series of tilt rotor aircraft designs to meet various noise goals at minimum DOC. These vehicles were spaced across the spectrum of possible noise levels from completely unconstrained to the quietest vehicle that could be designed within the study ground rules. A group of optimization parameters were varied to find the minimum DOC while other inputs were held constant and some external constraints were met. This basic variation was then extended to different aircraft sizes and technology time frames. It was concluded that reducing noise annoyance by designing for lower rotor tip speeds is a very promising avenue for future research and development. It appears that the cost of halving the annoyance compared to an unconstrained design is insignificant and the cost of halving the annoyance again is small.

Acknowledgements

The author wishes to thank Mr. J. Rabbott and Mr. J. McCloud of NASA Ames for their general guidance and technical suggestions. He also wishes to thank Mr. W. Swan of the Flight Transportation Laboratory for writing and debugging the noise evaluation portion of the computer program, and Mr. M. Scully and Professor N. Ham of the VTOL Technology Laboratory at MIT for their numerous helpful suggestions in regard to the design portion of the computer program.

This work was performed under Contract NAS2-7620, DSR No. 81085, from the NASA Ames Research Center, Moffet Field, California.

1.0 Introduction

The tilt rotor VTOL aircraft configuration is a serious contender for a significant role in intercity public transportation in the future, particularly in densely populated regions. Like other rotary wing aircraft types, the tilt rotor is inherently relatively quiet due to its low disc loading and low flow velocities in and around the propulsion device. However, commercial rotary wing aircraft may have to be quieter in the future to achieve community acceptance. This is particularly true in the case of intercity service which would involve large vehicles and high frequency of operations at some terminals. Because of the small size of the vertiport, the aircraft operations are closer to the surrounding non-user population. Furthermore, it may be necessary for economic reasons to locate terminals in areas having a relatively low background noise level, such as residential areas.

In order to assess the potential of tilt rotor aircraft as a viable part of the intercity transportation system, it is necessary to know what degree of noise reduction can reasonably be expected in the future. In other words, the relationship between noise reduction and cost increases must be known. There are two methods of reducing the noise exposure due to aircraft operations, changes in flight profile and changes in design. The aircraft trajectory can be moved further from the listeners, the amount of noise generated can be reduced by

reducing thrust, or the speed can be increased in order to reduce noise exposure. This method of noise reduction is explored for VTOL aircraft in references 1 and 2. This method does not generally have a significant impact on direct operating cost (DOC). The second method is to change the design of the aircraft to reduce the noise generated at a given distance, thrust level, and speed. This is the method considered here.

Design changes for noise reduction in tilt rotor aircraft are discussed in Ref. 3 in considerable depth. Design changes in a 12,000 lb gross weight aircraft were considered there, both from the military point of view (to reduce aural detectability) and the commercial point of view (to reduce noise annoyance). It was found that reduction of the rotor tip speed used in the helicopter mode and conversion is the most effective means of reducing noise annoyance. Other design changes which were considered include variations in number of blades, blade tip shape, blade planform, blade airfoil section, blade twist, and blade spacing. It was found that dramatic noise reductions cannot be accomplished with these changes. It appears that they would also not generally result in a dramatic change in DOC. Therefore these types of changes were neglected in the work reported here.

The object of this study was to develop the relationship between direct operating cost and departure noise annoyance for tilt rotor aircraft. This was accomplished by generating a series of tilt rotor aircraft designs to meet various noise

goals at minimum DOC. These vehicles were spaced across the spectrum of possible noise levels from completely unconstrained to the quietest vehicle that could be designed within the study ground rules. A group of optimization parameters were varied to find the minimum DOC, while other inputs were held constant and some external constraints were met. This basic variation was then extended to different aircraft sizes and technology time frames. This study is analogous to the one conducted previously by the Flight Transportation Laboratory for helicopters (Ref. 4). However, unlike the helicopter work, this study used a single measure for evaluating total community annoyance due to a departure operation.

2.0 Design Procedure

In this study a large number of tilt rotor aircraft designs were created with the aid of a preliminary design computer program (Ref. 5). The purpose of this preliminary design program is to rapidly obtain parametric variations of the design for a set of particular requirements. The program does not internally optimize the design; this is done by the user. The program takes as input a set of design parameters sufficient to fix the design. It then performs the normal preliminary design calculations to obtain both the other design parameters of interest and various figures of merit. Figures of merit include performance parameters such as speed and payload-range, direct operating cost, and noise annoyance. The noise annoyance portion is the subject of section 3.

2.1 Program Description

A flow chart of the preliminary design computer program is shown in Fig. 1. The program begins by reading input data. Various parameters which are independent of gross weight are then calculated: atmospheric properties, fuselage profile drag and constant weights.

Then the program goes into a design procedure which is an iteration on gross weight. Initially a gross weight is estimated from the constant weights; on succeeding iterations a new gross weight is found from those of the preceding two iterations.

Fig. 1 Computer program flow chart

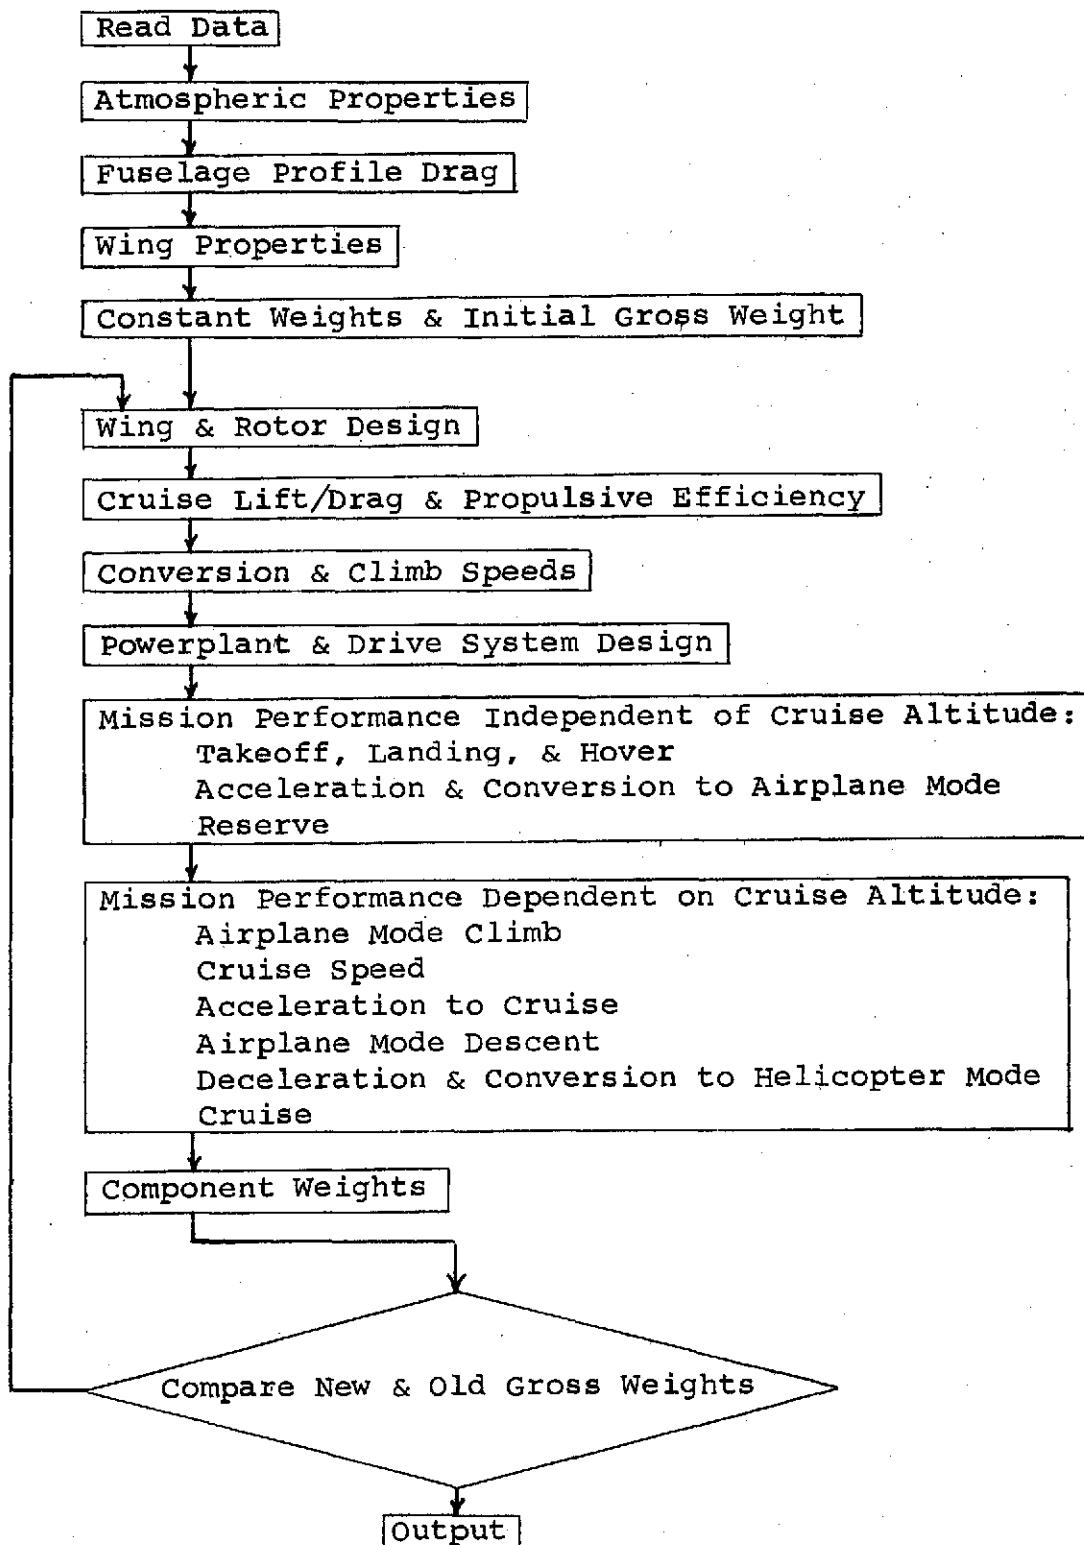

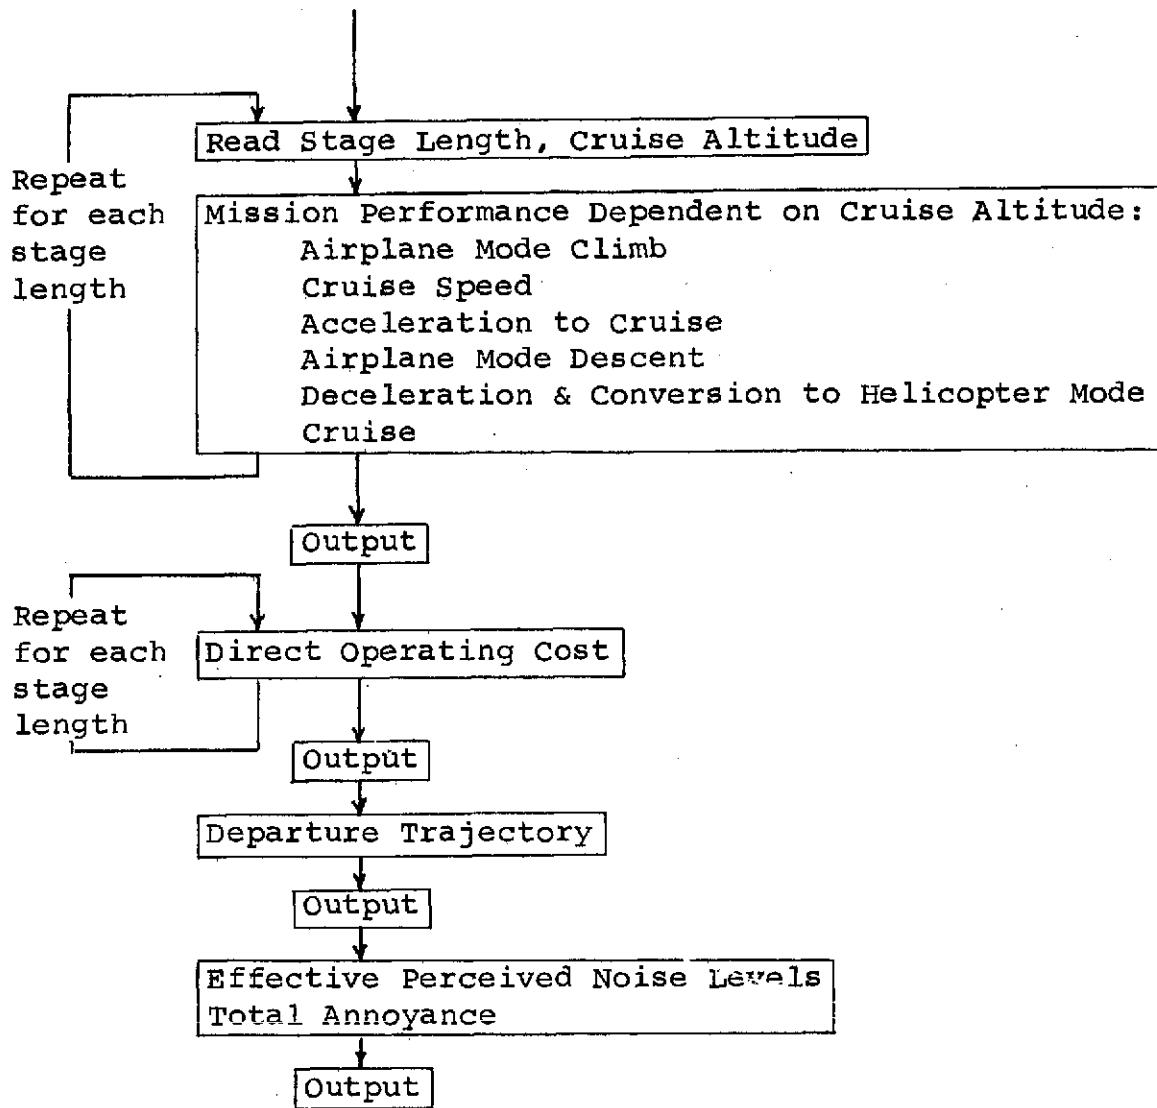

Fig. 1 Computer program flow chart (cont'd)

Next the rotors and wing are sized. The rotor radius is found from the input disc loading. The wing span is based on rotor-fuselage clearance. The wing loading is input and the area and aspect ratio are calculated. The hover thrust coefficient is found, using the input tip speed and corrected for wing download. Then the rotor solidity is found using the input thrust coefficient to solidity ratio (C_T/σ).

The cruise lift to drag ratio is found from the wing and fuselage geometry. Then the cruise propulsive efficiency of the rotors is calculated according to an empirical formula from the cruise forward Mach number, the cruise tip Mach number, and the rotor solidity.

Next the airplane mode best rate of climb speed is calculated. Then the conversion speed and airplane mode wing lift coefficient are calculated, corresponding to the input helicopter mode maximum advance ratio. This lift coefficient and the ratio of the airplane mode best rate of climb speed to the conversion speed are output to evaluate conversion performance.

Then the powerplant is sized to the maximum of the requirements for emergency hover, conversion and cruise. The emergency hover requirement is for one engine out hover on a hot day at an input altitude. The conversion requirement is established by an input conversion power factor (labelled "Excess Factor Hel Mode" in the output) which is the ratio of conversion power desired to normal hover power. Power

is corrected for temperature, altitude, forward speed and r.p.m. It is assumed that the engines operate at rated r.p.m. in hover and a penalty is accepted for any reduction in r.p.m. in the airplane mode. This completes the selection of design parameters.

The aircraft is then flown through the design mission to find the fuel consumed. The assumed mission profile consists of ten phases: takeoff, acceleration and conversion to the airplane mode, airplane mode climb, acceleration to cruise speed, cruise, airplane mode descent, deceleration and conversion to helicopter mode, hover, landing, and reserve. The portion which is independent of cruise altitude is done separately, so that it will not be repeated in the stage length variation later. The fuel burn rate is corrected in each phase for power setting, r.p.m., forward speed and altitude. Optional provision is made for the aircraft to obey the FAA speed limit of 250 kt. IAS below 10,000 feet. If the aircraft has more installed power than that required for cruise at design cruise speed, and if the drive system and rotor limits permit, then the aircraft is allowed to cruise faster, up to these limits. Cruise fuel is calculated according to the Breguet method.

Then the component weights are calculated. Both the rotor and drive system weights are taken to be the highest resulting from helicopter mode and airplane mode design requirements considered separately. If the rotor hover coning angle exceeds 8.5° , weight is added to approximate tip weight

and blade weight necessary to reduce coning to this amount. Here it is assumed that the rotor is of the gimballed type having a first flatwise bending mode frequency of 2 per rev. The wing weight is independent of flap area, but is adjusted for the lift coefficient required in conversion.

Now the component weights and fuel weights are summed, which results in a new gross weight. If the difference between the new and old gross weights is greater than ten pounds, the design procedure goes through another cycle. When the iteration is complete, the parameters describing the final design are printed.

The vehicle is then flown through various input stage lengths which are less than the design range, with appropriate input cruise altitudes. The time, distance and fuel for each stage is calculated and printed. Then the program calculates the direct operating cost (DOC) for each stage length, by category, and prints this out. The DOC is calculated according to the Lockheed/New York Airways formula. (Ref. 6)

2.2 Calibration

In order to calibrate the computer program, the program was used to produce approximations of two existing tilt rotor designs. These were the Bell D302 (Ref. 7) of 44,100 lb gross weight and the Vertol 215 (Ref. 8) of 67,000 lb gross weight. These designs were picked because they represent the experience of

two different firms and they are near the middle of the size range of interest. Both were configured as transport aircraft. However they were designed to meet military requirements which compromised their effectiveness as commercial aircraft. By making allowances for the military requirements in the inputs to the computer program, good agreement with the original designs was obtained. Both of these designs are intended to represent approximately 1975 technology, and therefore the values of the technology factors which gave the best agreement in the calibration were considered to be 1975 values.

3.0 Noise Evaluation Procedure

The arrival, or descent and landing, operation of a tilt rotor aircraft may generate slightly greater community annoyance than the departure, or takeoff and climbout, operation. There are two aspects of the descent and landing operation that account for the asymmetry between the two. First, there may be more blade/wake interaction in the helicopter mode descent than in climb, depending on the exact trajectory. Second, the descent must be constrained to avoid the vortex ring state and inability to control the descent. Thus the annoyance produced by the descent and landing is more dependent on operational considerations than on design parameters. The annoyance produced by the takeoff and climbout, on the other hand, is strongly dependent on operational considerations than on design parameters. Many of the design changes which reduce departure noise will also reduce arrival noise. For these reasons, departure annoyance was considered more appropriate for this study of noise reduction through design changes.

3.1 Departure Path

After the direct operating cost portion of the computer program, the departure trajectory to 10,000 feet altitude is calculated in detail. The result is a time history of the distance, altitude,

flight path angle, thrust and rotor tilt angle relative to the flight path. This history then is input to the noise annoyance calculation.

The departure path is shown schematically in Figure 2. Throughout this path acceleration is constrained by power available. There are three other constraints for passenger comfort. The acceleration builds up smoothly over a specified time to its allowable input maximum, which is used for all phases of flight. The rate of rotation of the acceleration vector after obstacle clearance is specified. Finally, the maximum fuselage pitch angle is specified.

To determine the departure path prior to the airplane mode climb, the program considers steps in velocity, of input size, and calculates the acceleration magnitude according to the routine shown in Figure 3. The rotor tilt angle is first found from the balance of forces perpendicular to the acceleration vector and the power limited acceleration magnitude is found from the force balance parallel to the acceleration vector. If the power limited acceleration is larger than the allowable acceleration, the force balances are set up again and solved for the thrust and a new tilt angle. The time, distance, altitude, and flight path angle are found from the acceleration and velocity. The forces and angular relationships are shown in Figure 4. The nomenclature is given in Table 1.

A simple model is used to predict the performance of the

rotor and wing through the complete range of rotor tilt angles. Elementary helicopter blade element and momentum theory formulae are used to find the rotor thrust, since the advance and inflow ratios are not large. To predict the wing forces, it is assumed that the flow through the rotor is fully developed when it reaches the wing. Hence the portion of the wing that is influenced by the rotor is that portion which is overlapped by the inner half of the disc area. On this portion of the wing the total slipstream velocity is assumed to be the vector sum of the free-stream velocity and the fully developed induced velocity of the rotor. The optimum flap deflection cannot be conveniently found, so it is assumed to be equal to the flight path angle. The aircraft is assumed to be pitched up to the input maximum, or until the angle of attack of the rotor-influenced portion of the wing is 3° less than stall, whichever is less, until the aircraft reaches the speed where the wing lift is equal to the gross weight.

Conventional fixed wing methods are used to calculate performance at the beginning of the airplane mode climb and at 10,000 ft. altitude.

3.2 Noise Prediction

Noise nomenclature is given in Table 2. There are three significant sources of noise in the tilt rotor vehicle: the engines, the drive system and the rotors. The noise from the

engines can generally be reduced to less than that from the rotors in a quite straightforward manner, as discussed in Ref. 3. The weight penalty for quieting the engine and drive system below the rotor noise level is accounted for by increasing the engine installation weight factor (FENGI) if the 500 ft. side-line noise level (SEL) is below 95 EPNdb. In the absence of adequate empirical data, the author's engineering judgement was used to obtain the following relationship: The engine installation factor was kept at 1.50 at 95 EPNdb and was assumed to be 1.60 at 87 EPNdb and 2.00 at 80 EPNdb. A parabolic curve was fitted between these points.

Rotor noise is predicted using helicopter methods because only low disc loading and forward speeds are considered. Helicopter rotor noise is usually classified into three categories: blade slap or impulsive noise, rotational or discreet frequency noise, and vortex or broadband noise. The understanding of the mechanisms of rotor noise is rapidly evolving and this classification has been questioned. However, it remains the most useful one for the moment.

Blade slap is by far the most offensive of these types of noise when it occurs. (Ref. 12) It can occur in high speed helicopter flight due to compressibility phenomena in the vicinity of the advancing tip, (most frequently on two bladed rotors) or it can occur at low speed due to interaction

between a blade and the tip vortex of another blade. The former mode should not be a problem in commercial operation of tilt rotor aircraft because there should be no need to operate at high speed in the helicopter mode. Since there is no rotor overlap in the tilt rotor the latter mode should be limited to descent conditions where the wake does not leave the rotor disc rapidly. This noise generation mechanism is not strongly dependent on design parameters, but more on operational considerations. Because it is not likely to occur in the departure operation, it is neglected in this study.

Rotational noise will result because the pressure field around a rotor or propeller blade will change periodically relative to a stationary observer. The fundamental frequency is the blade passage frequency, which is very low (less than 20Hz.) for most rotary wing aircraft. The rotational noise spectrum consists of a series of discrete tones, starting at the fundamental and decreasing in amplitude as frequency increases. Since precise prediction of higher harmonic airloading is generally not possible, a partly empirical prediction method must be used. Unfortunately the body of experimental data is very small, and hence the process of deriving a prediction method is not unique. Nevertheless, there is a commonly accepted prediction method (Ref. 9). Using this method for typical rotary wing aircraft, it is found that rotational noise is significant compared to vortex noise only at high advancing tip Mach numbers in the helicopter mode or if the noise is calculated at large distances

from the vehicle. The former condition is not likely to apply to the tilt rotor aircraft in commercial operation. In the latter case the overall noise level has dropped below the background level assumed in this study. For these reasons rotational noise is neglected.

Vortex noise arises from two sources: random airloads on the blades and turbulent flow in the blade wakes. The vortex noise spectrum consists of a continuous broad hump with a peak generally in the range of 200-600 Hz. A reasonably reliable method for predicting vortex noise has been developed (Ref. 10 and 11). Overall sound pressure level (SPL) at 300 feet is given by the following formula:

$$L_p = 10 \log_{10} \frac{7.62 \times 10^{-10} T^2 (V_{tip})^2}{\rho^2 A_b}$$

The complete spectrum is predicted from the figure developed empirically by Schlegel for an unstalled rotor blade (Ref. 10).

It is then necessary to correct for the sensitivity of the human aural system; this is normally done by conversion to Perceived Noise Level (PNL). It is recognized that none of the currently accepted corrections take adequate account of the annoying nature of very low frequency sounds or amplitude modulation typical of helicopter noise spectra. Improvement in these corrections must await new subjective testing. Following unpublished work by Anthony Hays at the M.I.T. Flight Transportation Lab, the spectral distribution in SPL and the corresponding weighed and combined PNL measures were calculated for the range of base frequencies of 100-400 Hz. over distances from 100 to 20,000 ft.

It was found that the combined effect of the conversion from SPL to PNL and the losses and changes in emphasis due to atmospheric absorption could be approximated within a decibel by the formula

$$L_{PN} = L_P + 3.0 - 0.000375 * d$$

This held good for SPL ranges from 120 - 80 db, and was conservative in the 80-70db range. The formula was valid only for distances greater than 2000 ft. Within 2000 ft. a correction which depended upon the peak frequency was necessary.

$$L_{PN} = L_P + 3.0 - 0.000375 * d + 0.0264 f_{peak} (1 - d/2000)$$

The peak frequency is the Strouhal frequency given by the following approximation for $\alpha = 6^\circ$

$$f_{peak} = \frac{0.28 (V_{tip}/\sqrt{2})}{t \cos \alpha + c \sin \alpha} \approx V_{tip}/c$$

Distance attenuation is simply the dilution of sound energy by spreading over larger spherical surface areas as the distance from the source increases. Thus, if the standard distance is 300 ft., the energy levels at other distances are reduced by the ratio of the squares of the distances, or 6 decibels per doubling of distance.

There is in addition an adjustment to the local perceived noise level due to different viewing angles from the rotor shaft. Reference 9 gives the formula for the adjustment in decibels,

$$DIR = 10 \log_{10} \left[\frac{\cos^2 \phi + 0.1}{\cos^2 70^\circ + 0.1} \right]$$

The conversion from perceived noise level (L_{PN}) to effective perceived noise level (L_{EPN}) involves converting the L_{PN} measure to energy units, multiplying by the duration, and dividing by the standard time, 10 seconds. Thus

$$10(L_{EPN}) = \sum_{\text{all DT}} (10^{(L_{PN}/10)} * DT/10)$$

3.3 Annoyance Prediction

The annoyance measure is based on the work of Ref. 13. The noise annoyance routine calculates Effective Perceived Noise Level at a large number of points on a grid representing the area on one side of the flight path. The noise pattern is symmetrical. The EPNL at each point is then converted to personal annoyance units,

$$\text{Annoyance} = 10^{(L_{EPN} - \text{cutoff})/33.2}$$

Because this measure is asymptotic to zero the cutoff noise level must be above the background noise level. Here this difference is assumed to be 10 EPNdB which is consistent with the normal fluctuation of the background level. The annoyance value is one at the cutoff and zero below. The land use pattern and cutoff levels used in this study are shown in Figure 5.

The personal annoyance is then integrated over the population surrounding the airport. Since the population density is assumed constant it does not appear explicitly. The annoyance value at each point is multiplied by the surrounding land area and the results are summed to obtain the total community annoyance from

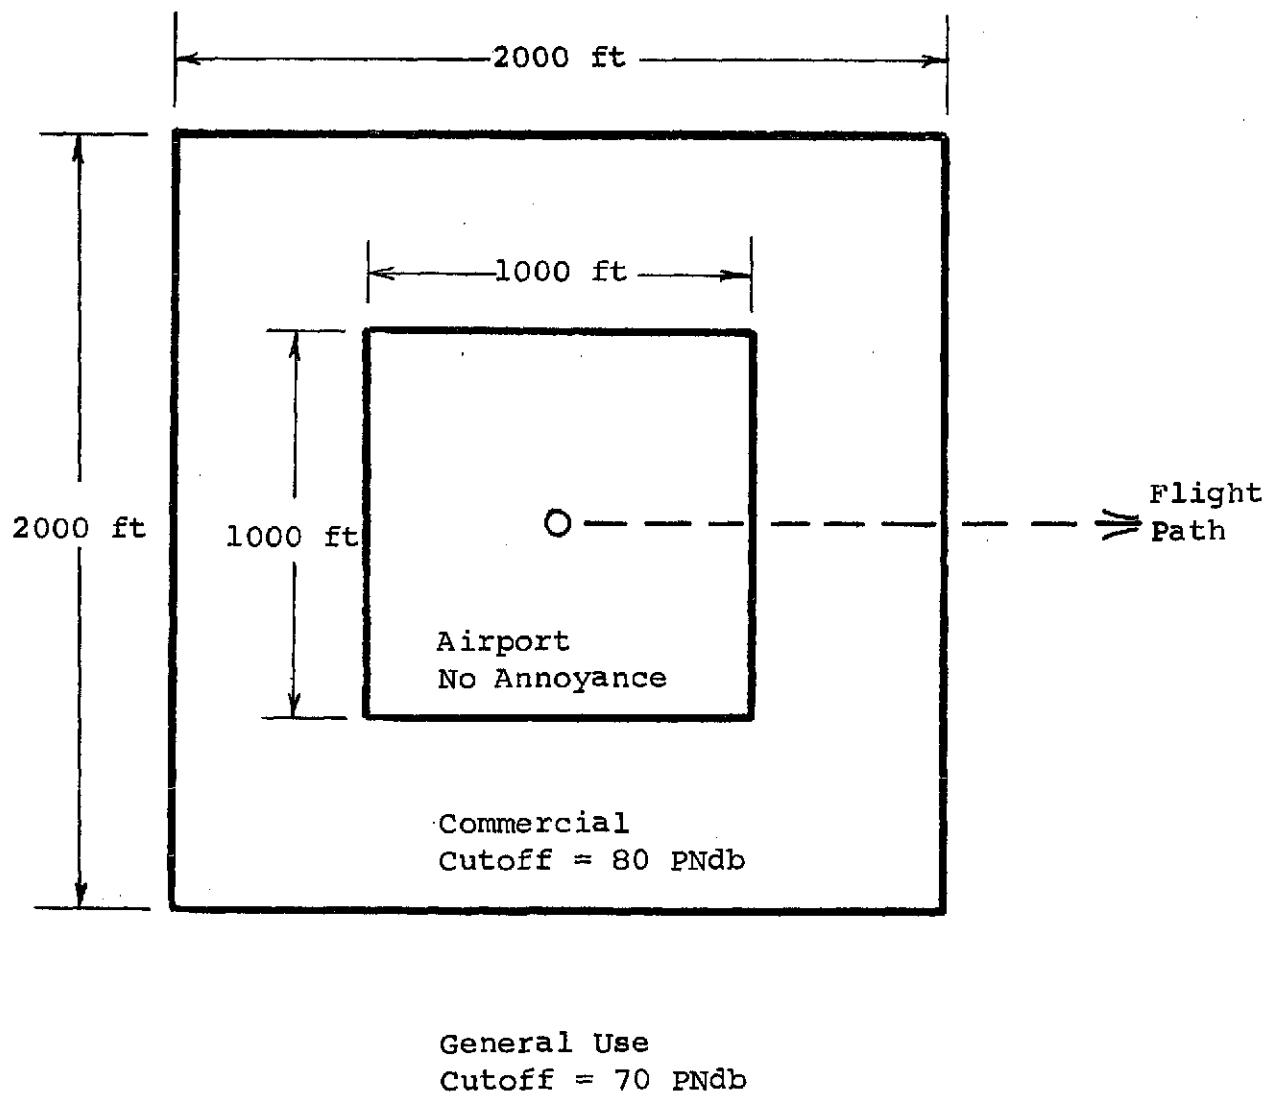

Fig. 5 Land use plan

a single departure.

Unlike other measures, this community annoyance measure obeys the following simple rules:

- 1) A sound 10 EPNdb louder is twice as annoying.
- 2) A noise quieter than the background noise level produces no annoyance.
- 3) The total annoyance resulting from two people listening to a noise is twice the annoyance of one person listening to the same noise.

4.0 Study Method and Ground Rules

4.1 Variations

The basic variation consisted of five aircraft designs of 1980 time frame having 50 seats. These vehicles were spaced across the spectrum of possible noise levels, from completely unconstrained to the quietest vehicle that could be designed within the study ground rules. The noise goals that were used for design optimization were in terms of Effective Perceived Noise Level at 500 feet side line, while the total noise annoyance was used for comparing optimum designs. The tilt rotor designs generated in this study are designated by codes consisting of a letter mnemonic indicating the noise class, a number indicating the time frame and a number indicating the size in terms of passenger seats. The basic variation aircraft and their noise goals are shown in Table 3. The parameters that were varied to find the minimum DOC aircraft for each noise goal are shown in Table 4, along with the approximate range over which they were varied. The final optimal values of these parameters are given in Table 10, section 5.

In the size variation the basic variation was repeated for sizes of 20, 80 and 110 seats. The gross weight did not converge for S-80-110, as discussed in Section 5, so it is not included here. In the timeframe variation the basic variation was repeated for time frames of 1975 and 1985. In this study, the time frame is intended to be the year of initial prototype flight

Table 3 Basic Variation Noise Goals

testing, with airline service following two to five years later. The values of the parameters which were changed to produce the size and time frame variations are given in Tables 5 and 6, respectively. The 1975 values of the parameters used in the time frame variation are based on the calibration of the computer program as discussed in Section 2. The 1980 and 1985 values were derived using the author's judgement and knowledge of projected technological developments to extrapolate historical trends. The optimality of the values of the optimization parameters found in the basic variation was checked by varying each of these parameters singly for extreme points of the size and time frame variations, namely C-75-20, C-80-110, S-80-80, C-75-50, and S-85-50, S-75-50, and S-85-50. No significant improvements could be found so these parameters were kept constant for each noise class throughout the size and time frame variations.

In all the previous variations the obstacle clearance path was kept fixed at 60° to 100 ft. In order to assess how this choice of path might affect the results, the obstacle clearance path was varied. Eight other departure paths were considered with obstacle heights of 50, 100 and 200 feet and obstacle clearance angles of 30°, 60° and 90°. It was found that the basic variation aircraft did not have sufficient power in the conversion phase to execute the departure paths having greater obstacle heights or steeper obstacle clearance angles. The reason for this is the assumption in the departure path calculation that that the vertical speed built up in the obstacle clearance phase is maintained through the acceleration and conversion phase.

Table 5 Design Parameters Varied with Size

Parameter	20	50	80	110
Cabin Crew	0	1	2	3

Rotor Weight Technology Factor	1.05	1.00	.95
Drive System Weight Technology Factor	0.85	0.83	0.81
Engine Power/Weight, hp/lb	7.0	8.5	10.0

The higher paths require that conversion be executed while maintaining a greater vertical speed requiring extra power which the basic variation aircraft do not have. Therefore the path variation was accomplished using a more powerful aircraft, QP-80-50. This design is similar to Q-80-50 but the conversion power factor has been increased from 1.40 to 2.00.

Finally a hovering case was run to develop a standard level of total annoyance. A vehicle was found which generated 95.0 PNdB at 500 ft. distance while hovering at 100 ft. altitude. This is approximately the noise level of the Vertol 347 helicopter. Then this vehicle was hovered over the center of the vertiport for one minute at 100 ft. altitude to obtain a standard level of total annoyance. All gross levels of annoyance produced by other vehicles were divided by this value to obtain relative annoyance, which is used for all plots.

4.2 Constraints

Several constraints, which are external to the computer program, were obeyed during the variations described above. A rotor solidity of 0.25 was considered the arbitrary maximum. The wing aspect ratio was kept below 8.0 to avoid aeroelastic problems. The wing loading was kept above 50 to permit reasonable ride quality. Finally the conversion speed was not permitted to be less than two thirds of the airplane mode best rate-of-climb speed, in order to have an adequate conversion corridor.

4.3 Constants

The values of significant constants which were used throughout the study are shown in Tables 7, 8 and 9. Complete data on all the aircraft designs discussed in this report is presented in Appendix 1. Direct operating cost was calculated at a variety of stage lengths. The cost over two 200 mile segments, with the engines not shut down at the intermediate stop, was selected as representative of typical high-density short haul operations. DOC is in 1973 dollars.

5.0 Results and Discussion

The basic variation resulted in five aircraft covering the spectrum of noise levels, but designed to common ground rules as discussed in Section 4. The basic variation includes only 1980 50 seat aircraft. The principal characteristics of these aircraft are shown in Table 10. For comparison the principal characteristics of QP-80-50, and of the hover example aircraft are given in Table 11. The rotor and wing planforms are shown in Figure 6. DOC is plotted vs. relative annoyance for the basic variation in Figure 7. This curve is the central result of this study. DOC for other stage lengths can be found from Figure 8. Complete information on all the aircraft designs discussed in this report is given in Appendix 1. Effective Perceived Noise Level Maps for basic variation aircraft are given in Appendix 2.

Starting with C-80-50 and moving downward in noise level, we see that each step cuts the relative annoyance roughly in half. M-80-50 differs from C-80-50 mainly in helicopter mode tip speed and solidity, and the resulting change in DOC is very small. Going on to Q-80-50, we see that now airplane mode tip speed and wing loading are also reduced, resulting in a slightly greater change in DOC. With D-80-50 cruise speed is added to the list of changing fundamental parameters and DOC begins to rise more sharply. Finally, in S-80-50 the effects of further changes in all these parameters combine to give a sharp increase

in gross weight and a large increase in DOC. This vehicle is up against all the constraints discussed in Section 4. Thus it is appropriate that the slope of the DOC vs. relative annoyance curve in Figure 7 is nearly infinite at this point.

In the size variation, the basic variation was extended to include 20, 80 and 110 seat sizes. The gross weight did not converge for S-80-110, because the rotor weight penalty to prevent excessive coning at low tip speeds increases rapidly with aircraft size. DOC is plotted against relative annoyance for each size in Figure 9. However, it is appropriate when comparing the noise annoyance of aircraft of varying size to consider the annoyance per seat, since fewer departures would be required to transport a given number of passengers on larger aircraft. Thus DOC is plotted vs relative annoyance per seat in Figure 10. It can be seen that the minimum DOC aircraft decreases in size as the permissible annoyance is reduced. The 110 seat aircraft has the lowest DOC over most of the annoyance range but it is interesting to see how close the 50 seat and 80 seat aircraft are in DOC. The effect of frequency on demand would favor smaller aircraft, and hence the best aircraft from the airline system point of view is probably smaller than 80 seats. Also the curves indicate that DOC would not decrease significantly for aircraft larger than 110 seats.

In the time frame variation, the basic variation was extended forwards and backwards in time, from 1980 to 1985 and 1975. DOC is plotted against relative annoyance for each time frame in

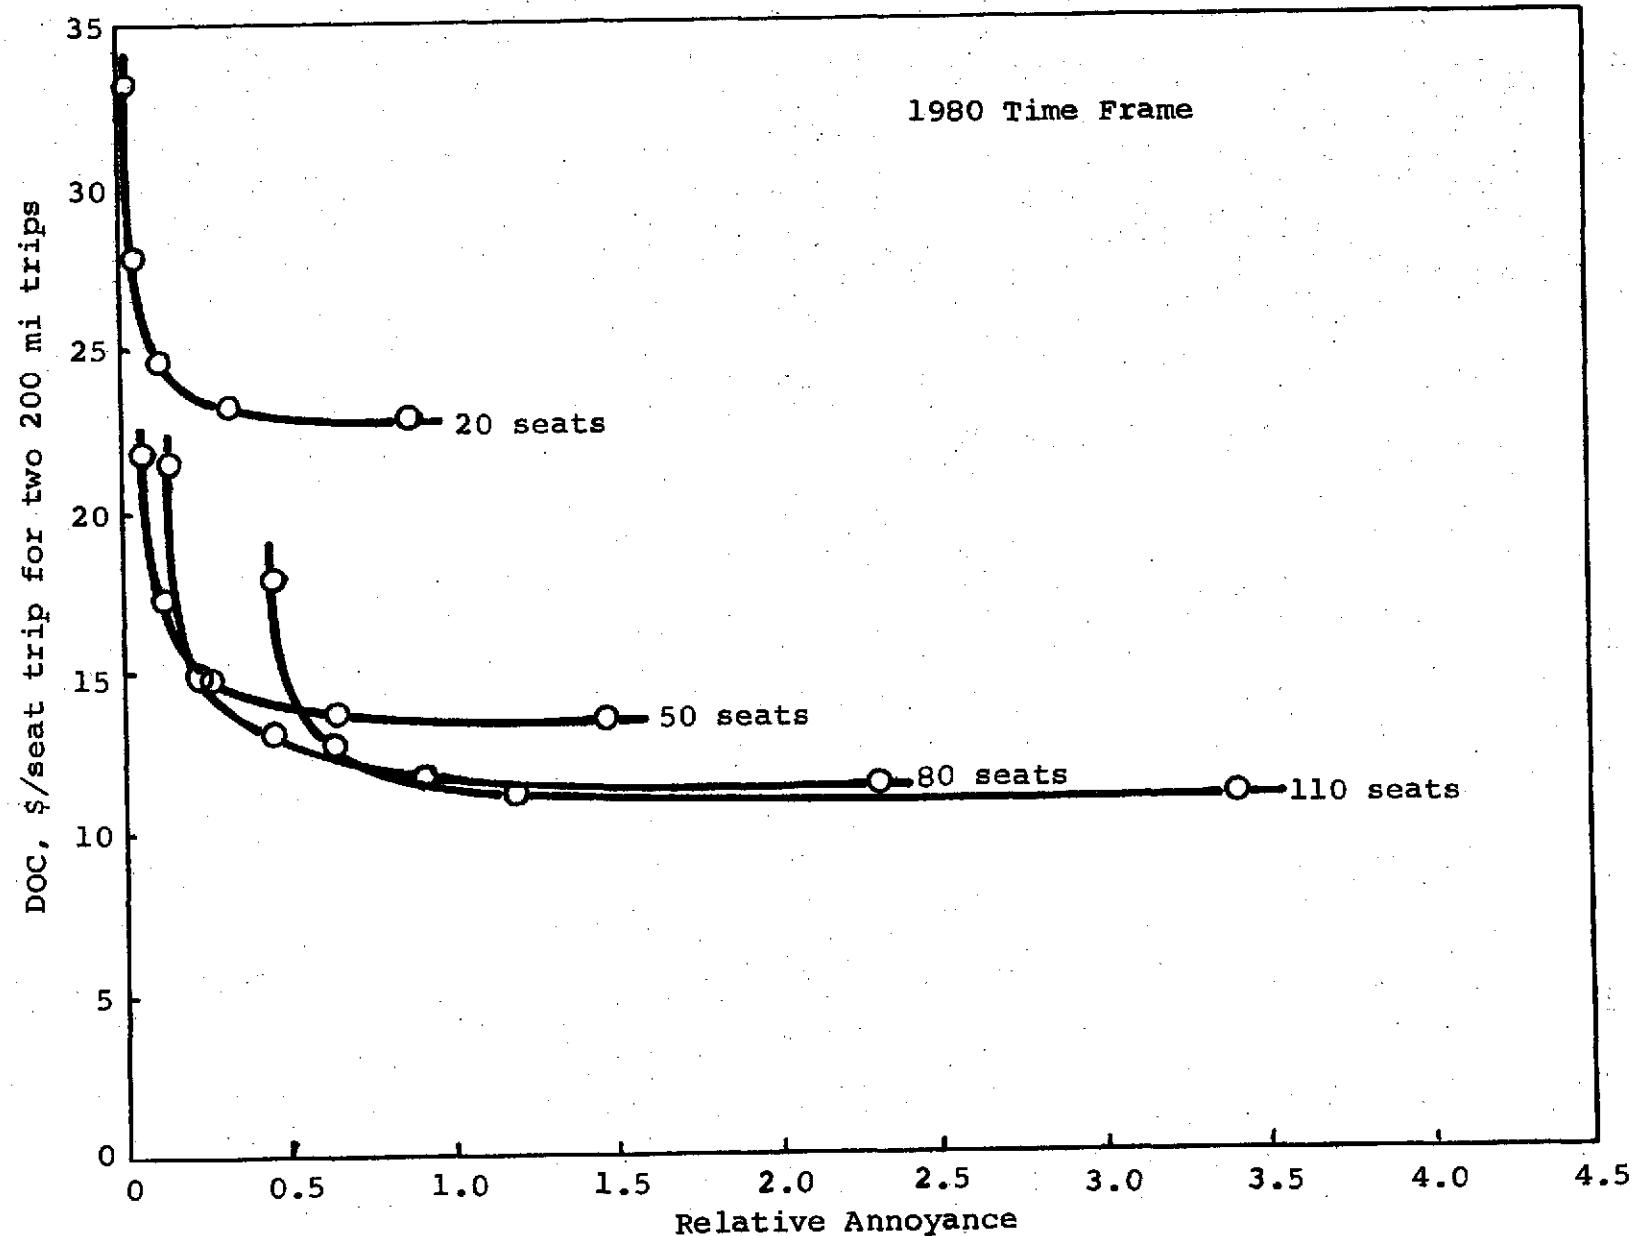

Fig. 9 Size variation - DOC vs relative annoyance

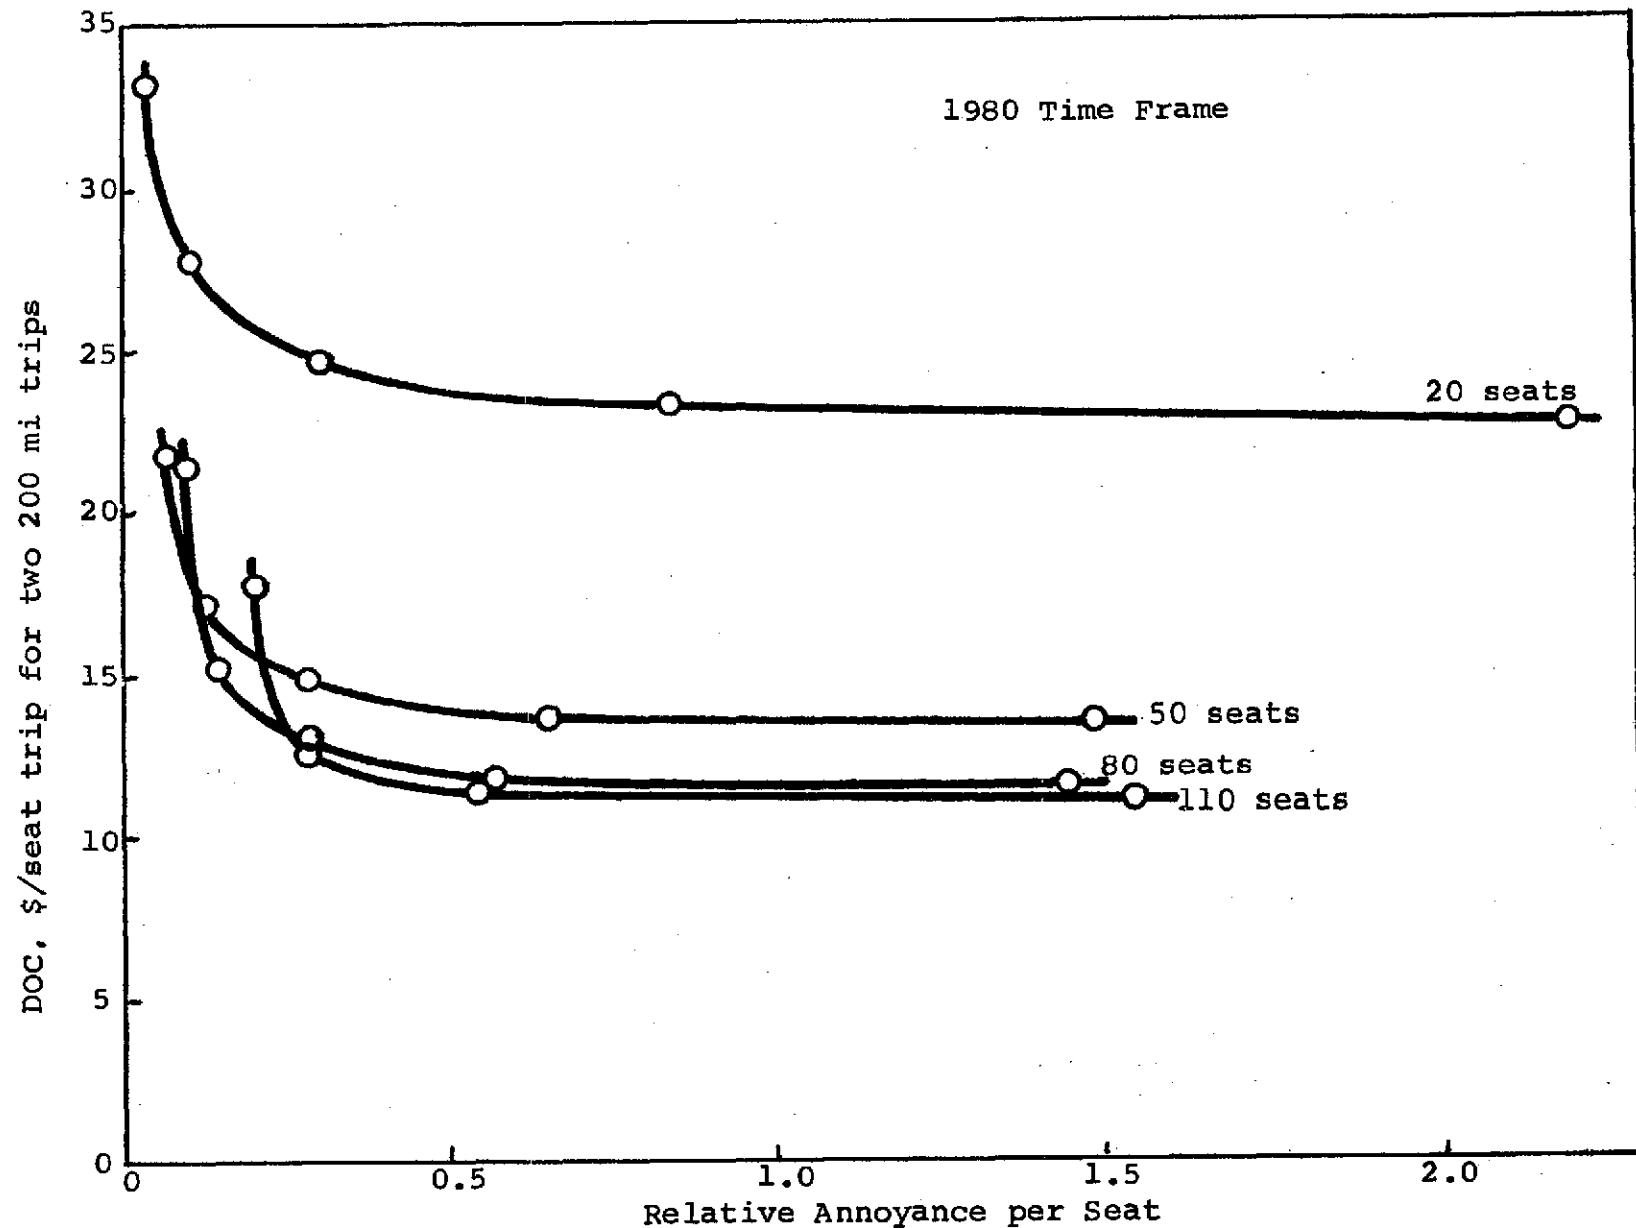

Fig. 10 Size variation - DOC vs relative annoyance per seat

Figure 11. The curves fall rather close together, reflecting a fairly small advancement in aircraft technology over this time period. However, over most of the annoyance range, moving ahead in time can produce a substantial reduction in annoyance at constant DOC.

The path variation was accomplished with an aircraft, QP-80-50, which is similar to Q-80-50 but the conversion power factor was increased from 1.40 to 2.00, as discussed in Section 4. Nine different departure paths were used with obstacle heights of 50, 100 and 200 feet and obstacle clearance angles of 30° , 60° , and 90° . The results are plotted in Figure 12. From these curves it can be seen that higher departure paths produce greater annoyance, but annoyance is not very sensitive to the height of the path. To explore this further, the highest, middle and lowest paths are shown in Figure 13. Although the middle path in this figure is approximately twice as high as the lowest one, it takes longer to execute resulting in the annoyance being increased about 15%. The same thing can be said with respect to the highest and middle paths. This is in agreement with Ref. 14. There it was shown that higher flight paths result in substantial reduction of the areas within contours of Perceived Noise Level. However, when these values were adjusted for the duration of the noise, the area within most contours of Effective Perceived Noise Level was slightly increased.

6.0 Conclusions

The central conclusion of this work is that reducing the noise annoyance of commercial tilt rotor aircraft by designing for lower rotor tip speeds is a very promising avenue for future research and development. It appears that the cost of halving the annoyance compared to an unconstrained design is insignificant and the cost of halving the annoyance again is small.

Designing for noise reduction biases size selection in favor of smaller designs and the decrease in DOC for sizes over 80 seats is small. Improvements in aircraft technology in the next ten years will offset the cost of considerable noise reduction. The noise annoyance is not very sensitive to choice of departure path but higher departure paths produce slightly greater annoyance.

The principal limitation of this study is the state of the art regarding low tip speed, high solidity rotors. The prediction of performance, weight, and noise generation are all based on substantial extrapolations of data on existing rotors. There is a critical need for research in this area if commercial tilt rotor aircraft are going to have a small noise impact. If the noise impact is not small these aircraft will probably not be viable.
